- 1 Explain Path Loss model for free space propagation along with equations. 10
 - Path loss is defined as the difference (in dB) between the effective transmitted power and the received power
 - Free-space path loss is defined as the path loss of the free-space model PL(dB)=10 $log(Pt/Pr)=-10 log(GtGr\lambda 2)/(4\pi) 2d2$
 - The gain of an antenna G is related to its affective aperture Ae by $G=4\pi Ae$ / $\lambda 2$ where Ae is related to the physical size of the antenna, λ is related to the carrier frequency ($\lambda=c/f=2\pi c$ / ωc) where f is carrier frequency in Hertz, c is speed of light in meters/sec o ωc is carrier frequency in radians per second
 - Friis free space model is only valid to predict "Pr" for the values of "d" which are in far-field from transmitting antenna
 - The far-field or Fraunhofer region of a transmitting antenna is defined as the region beyond the far-field distance df given by: $df = 2D2/\lambda$, D is the largest physical dimension of the antenna o Additionally df >> D
- Explain the two-ray model of ground reflection with proper diagrams and equations. 10

- 1. Free space propagation model is in accurate when used alone
- This model is found reasonably accurate when compared with the FSPL Model
- 2 ray model assumes both LOS and Reflected Signal for modelling the path loss

General Equation for Plane wave in free space is given by:

Assumptions:

- Height of the antenna are larger than the wavelength of propagating wave. i.e., h_t . h_r >> λ
- Height of the antenna are lesser than the T-R Separation.
 i.e., h_t · h_r << d
- Reflected waves are considered as gracing incidence waves
- 4. Lack of curvature of earth

Legend:

- 1. ht Height of Tx. Antenna
- 2. h. Height of Rx. Antenna
- 3. E_{LOS} E Field of LOS Signal
- 4. Eg E Field of Ref. Signal
- 5. d-(T-R) Separation

Parameters to be Estimated:

- E Field of Both Rays E_{los} & E_g
- 2. Path Difference (Δ)
- 3. Phase Difference (θ_{Λ})

Coefficient

4. Time delay (τ_d)

$$E(Z,t) = E_o \cdot e^{-\alpha Z} \cdot Cos(\omega t - \beta Z) \cdot \widehat{ax}$$

Let us rewrite the above equation with our own variables:

$$E(d,t) = \frac{E_{o}d_{o}}{d} \cdot Cos\left(\omega_{c}(t-\frac{d}{c})\right)$$

$$Cos\left(\omega_{c}t - \frac{d}{\omega_{c}}\right)$$

$$Cos\left(\omega_{c}t - \frac{d}{c}\right)$$

$$Cos\left(\omega_{c}t - \frac{d}{c}\right)$$

$$Cos\left(\omega_{c}t - \frac{2\pi d}{\lambda}\right)$$

$$Cos(\omega_{c}t - \beta d)$$

$$Cos(\omega_{c}t - \beta d)$$

$$Cos(\omega_{c}t - \beta d)$$

Calculating E Field (Etot):

Let us define the E field eqn. for LOS Signal and Reflected Signal:

 $E_{los}(d',t) = \frac{E_o d_o}{d'} \cdot Cos\left(\omega_c(t - \frac{d'}{c})\right) \qquad \text{(i)}$ $E_g(d'',t) = \Gamma \frac{E_o d_o}{d''} \cdot Cos\left(\omega_c(t - \frac{d''}{c})\right) \qquad \text{(ii)}$

An Ideal receiver just adds up all the received signal so the total E Field Eqn. is Given by:

$$|E_{tot}| = |E_{los}| + |E_a|$$

$$|E_{tot}| = \frac{E_o d_o}{d'} \cdot Cos\left(\omega_c(t - \frac{d'}{c})\right) + \Gamma \frac{E_o d_o}{d''} \cdot Cos\left(\omega_c(t - \frac{d''}{c})\right) - \left(\frac{11}{11}\right)$$

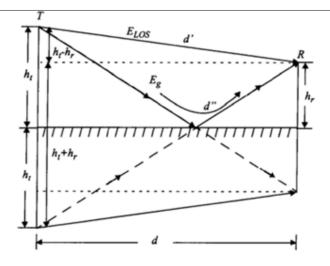

We know that from the laws of reflection in dielectrics, the reflection coefficient is (-1)

$$|E_{tot}| = \frac{E_o d_o}{d'} \cdot Cos\left(\omega_c(t - \frac{d'}{c})\right) + (-1)\frac{E_o d_o}{d''} \cdot Cos\left(\omega_c(t - \frac{d''}{c})\right) \qquad \qquad (|V|)$$

Using the method of images, Δ , between the line-of-sight and the ground reflected paths can be expressed as

$$\Delta = d'' - d'' = \sqrt{(h_t + h_r)^2 + d^2} - \sqrt{(h_t - h_r)^2 + d^2}$$

$$\Delta = d'' - d' \approx \frac{2h_t h_r}{d}$$

The combined E-field becomes

$$E_{\text{TOT}}(d,t) = E_{\text{LOS}}(d',t) + E_{\text{g}}(d'',t) = \frac{E_0 d_0}{d'} \exp\left(j\omega_c \left(t - \frac{d'}{c}\right)\right) - \frac{E_0 d_0}{d''} \exp\left(j\omega_c \left(t - \frac{d''}{c}\right)\right)$$

At some time, say at $t=d^{"}/c$

$$E_{\text{TOT}}(\overline{d, t = \frac{d''}{c}}) = \frac{E_0 d_0}{d'} \exp\left(j \frac{\omega_c \Delta}{c}\right) - \frac{E_0 d_0}{d''} - \left(\bigvee\right)$$

Also note that, when $d >> h_t + h_r$,

$$\left| \frac{E_0 d_0}{d'} \right| \approx \left| \frac{E_0 d_0}{d''} \right| \approx \left| \frac{E_0 d_0}{d} \right|$$

A mobile is located 5 km away from the base station and uses a vertical λ/4 monopole antenna with a gain of 2.55 dB, to receive cellular signal. The E field at 1 km away from the transmitter is measured to be 10–3 v/m, the carrier frequency is 900 MHz A] Find the length and the effective aperture of the receiving antenna. B] Find the received power at the mobile using 2 ray ground reflection model assuming height of 50 m and receiving antenna is 1.5m above the ground. 5+5

Given:

T-R separation distance = 5 km

E-field at a distance of $1 \text{ km} = 10^{-3} \text{ V/m}$

Frequency of operation, f = 900 MHz

$$\lambda = \frac{c}{f} = \frac{3 \times 10^8}{900 \times 10^6} = 0.333 \,\mathrm{m}.$$

Length of the antenna, $L = \lambda/4 = 0.333/4 = 0.0833 \text{ m} = 8.33 \text{ cm}$.

Gain of antenna =1.8 = 2.55 dB.

(b) Since $d \gg \sqrt{h_t h_r}$, the electric field is given by

The received power at a distance d can be obtained using equation (3.15)

$$P_r(d) = \frac{\left(113.1 \times 10^{-6}\right)^2}{377} \left[\frac{1.8 (0.333)^2}{4\pi}\right]$$

$$P_r(d=5 \text{ km}) = 5.4 \times 10^{-13} \text{ W} = -122.68 \text{ dBW or } -92.68 \text{ dBm}.$$

Explain (a) Delay Spread and Coherence Bandwidth (b) Doppler spread and Coherence Time (c) Angular spread and Coherence Distance -7

Find the Fraunhofer distance for an antenna with maximum dimension of 1m and operating frequency of 900MHz. If antenna have unity gain, calculate the path loss -3

- a) Delay Spread
- The delay spread is the amount of time that elapses between the echo (typically the first line-of-sight component and the last arriving) path.
- It is also referred to as the Multipath Intensity Profile, or power delay profile as it measures the multipath richness of channel.
- It specifies the duration of the channel impulse response h (τ, t) . **Delay spread** can be quantified through different metrics, although the most common one is the root mean square, the mean delay of the channel is:

$$\mu_{\tau} \, = \, \frac{\int_{0}^{\infty} \Delta \tau A_{\tau}(\Delta \tau) d(\Delta \tau)}{\int_{0}^{\infty} A_{\tau}(\Delta \tau) d(\Delta \tau)}$$

And the rms delay spread is given by :

$$\tau_{\text{rms}} = \sqrt{\frac{\int_{0}^{\infty} (\Delta \tau - \mu_{\tau})^{2} A_{\tau}(\Delta \tau) d(\Delta \tau)}{\int_{0}^{\infty} A_{\tau}(\Delta \tau) d(\Delta \tau)}}$$

The delay spread can be found by channel autocorrelation function A ($\Delta \tau$, 0) by setting $\Delta t = 0$.

- b) Coherence bandwidth B c -
 - Bandwidth over which the channel transfer function remains virtually constant.
 - Channel is considered relatively constant over the transmit bandwidth happens if the transmission BW < 'coherence' BW (i.e. Bc of the channel).
 - A signal sees a narrowband channel if the bit duration >> inter-arrival time of reflected waves ISI is small.
- c) Doppler Spread
 - In channels where transmitter and receiver move relative to each other the signal frequency is shifted depending on the velocity and as a result the spectrum of the narrowband signal

transmitted widens.

- This so-called Doppler effect can be observed on passing cars, moving stars and wireless communications.
- d) Coherence Time
- It gives the time period over which the channel is significantly correlated i.e. the time duration over which two received signals have a strong potential for amplitude correlation.
- Coherence time is actually a statistical measure of the time duration over which the channel impulse response is essentially invariant.

Mathematically

$$|t_1 - t_2| \le T_c \Rightarrow \mathbf{h}(t_1) \approx \mathbf{h}(t_2)$$

 $|t_1 - t_2| > t_c \Rightarrow \mathbf{h}(t_1)$ and $\mathbf{h}(t_2)$ are uncorrelated

Coherence time and doppler spread inversely related

$$T_c \approx \frac{1}{f_D}$$

- e) Angular spread
- It refers to the statistical distribution of the angle of the arriving energy.
- A large θ rms implies that channel energy is coming in from many directions, whereas a small θ rms implies that the received channel energy is more focused.
- A large angular spread generally occurs when there is a lot of local scattering, and this results in more statistical diversity in the channel
- f) Coherence Distance
- The coherence distance is the spatial distance over which the channel does not change appreciably.
- The dual of angular spread is coherence distance.
- As the angular spread increases, the coherence distance decreases, and vice versa.
- Mathematically: For Rayleigh fading which has a uniform angular spread

$$D_c pprox rac{.2\lambda}{ heta_{
m rms}}$$

Part 2 Solution:-

Given, an antenna with maximum dimension of 1 metre with operating frequency = 900 MHz. So, lambda =

 $c/f = 3*10^8/(900*10^6) = 0.33$ Far field distance = $2*D^2/lambda = 6m$.

5 Explain the three statistical channel model of a broadband fading channel

Rayleigh- and Rician-fading

- Consider two independent Gaussian random variables X and Y, both with mean zero and equal variance σ^2 . Then envelope $Z = \sqrt{(X^2 + Y^2)}$ is Rayleigh-distributed and Z^2 is exponentially distributed.
- For variance σ^2 for both $r_I(t)$ and $r_O(t)$ then signal envelope

$$z(t) = |r(t)| = \sqrt{r_I^2(t) + r_Q^2(t)}$$

is Rayleigh-distributed with distribution

$$p_Z(z) = \frac{2z}{P_r}e^{[-z^2/P_r]} = \frac{z}{\sigma^2}e^{[-z^2/(2\sigma^2)]}, z \ge 0,$$

$$P_r = \sum_n E[\alpha_n^2] = 2\sigma^2 \quad \text{average received signal power, i.e. received power}$$

$$P_r = \sum_n E[\alpha_n^2] = 2\sigma^2 \quad \text{average received signal power, i.e. received power}$$

$$\text{based on path loss and shadowing alone}$$

$$\text{For } z^2(t) = |r(t)|^2 \qquad p_{Z^2}(x) = \frac{1}{P_r} e^{-x/P_r} = \frac{1}{2\sigma^2} e^{-x/(2\sigma^2)}, \quad x \geq 0.$$

Thus, received signal power is exponentially distributed with mean $2\sigma^2$

When signal envelope |r(t)| & signal power $|r(t)|^2$ have above distributions, channel is said to be a Rayleigh-fading channel.

Nakagami fading

 The above Rayleigh and Rician models do not always fit experimental data. A distribution that has been empirically shown to fit data well is Nakagami fading distribution

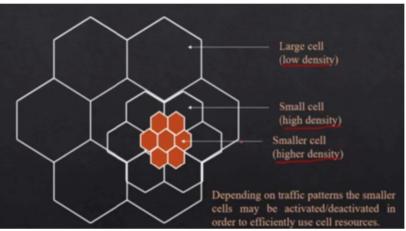

$$p_Z(z) = \frac{2m^m z^{2m-1}}{\Gamma(m) P_r^m} \exp\left[\frac{-mz^2}{P_r}\right], \quad m \geq .5 \quad \textit{P_r = average received power}$$

- Nakagami distribution is determined by its fading parameter m. For m=1, we get Rayleigh fading, and for $m=\frac{(K+1)^2}{2K+1}$, we get Rician fading. For $0.5 \le m \le 1$, we get fading that is "worse" than Rayleigh.
- · Power distribution for Nakagami fading is

$$p_{Z^2}(x) = \left(\frac{m}{P_r}\right)^m \frac{x^{m-1}}{\Gamma(m)} \mathrm{exp}\left(\frac{-mx}{P_r}\right)$$

7. Explain briefly about the cellular concepts

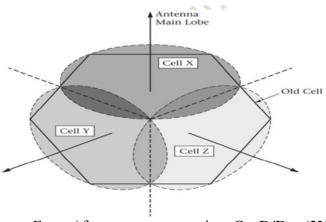

(a) Cell splitting

- It is the process of subdividing a congested cell <u>into smaller cells</u>. (each with <u>its own base station</u> and a corresponding reduction in antenna height and transmitter power).
- The increased no. of cells would <u>increase the no. of clusters</u> which in turn would <u>increase the no. of channels reused</u> and capacity.
- Each cell is divided into <u>six new smaller cells</u> with approximately <u>one-quarter the area</u> of the larger cells and use the same channel as shown in figure 3.4.
- To preserve the overall system frequency reuse plan, the <u>transmit power of these cells must be reduced by a factor of approximately 16 or 12dB</u>.

(b) Cell sectoring

Cell Sectoring - Uses directional antennas to effectively split a cell into 3 or sometimes 6 new cells.

- Reuse Factor/ frequency reuse ratio : $Q = D/R = (3N)^{\frac{1}{2}}$
- 3 directional antennas with 120° beamwidth to illuminate the entire area previously services by omnidirectional antenna
- Cell Sectoring provides co-channel interference reduction, hence S/I ratio increases.
- It does not require new cell sites and additional antennas and triangular mounting only.
- 6. Geometry as shown in the figure determine a) the loss due to knife edge diffraction and b) the height of the obstacle required to induce 6db diffraction loss. Assume f=900MHz.

$$\lambda = \frac{1}{3} = \frac{3 \times 10}{900 \times 10^{6}} = 0.333 \text{ m}$$

$$\lambda = \frac{1}{3} = \frac{3 \times 10}{900 \times 10^{6}} = 0.333 \text{ m}$$

$$\lambda = \frac{1}{3} = \frac{3 \times 10}{900 \times 10^{6}} = 0.333 \text{ m}$$

$$\lambda = \frac{1}{3} = \frac{3 \times 10}{900 \times 10^{6}} = 0.333 \text{ m}$$

$$\lambda = \frac{1}{3} = \frac{3 \times 10}{900 \times 10^{6}} = 0.333 \text{ m}$$

$$y = \tan^{-1}\left(\frac{75}{2\times10^3}\right)$$

$$x = \beta + y$$

$$y = \tan^{-1}\left(\frac{75}{2\times10^3}\right)$$

$$y = \cos^{-1}\left(\frac{75}{2\times10^3}\right)$$

$$\sqrt{2} = 0.04248 \left[\frac{2 \times 10 \times 10^3 \times 2 \times 10^3}{0.333 \left(10 \times 10^3 + 2 \times 10^3 \right)} \right]$$

$$\sqrt{3} = 4.24$$
